

Efficient Coordination in Weakest-Link Games

Arno Riedl, Ingrid M.T. Rohde, and Martin Strobel*

December, 2011

Abstract

Existing experimental research on behavior in weakest-link games shows overwhelmingly the inability of people to coordinate on the efficient equilibrium, especially in larger groups. We hypothesize that people will be able to coordinate on efficient outcomes, provided they have sufficient freedom to choose their interaction neighborhood. We conduct experiments with medium sized and large groups and show that neighborhood choice indeed leads to coordination on the fully efficient equilibrium, irrespective of group size. This leads to substantial welfare effects. Achieved welfare is between 40 and 60 percent higher in games with neighborhood choice than without neighborhood choice. We identify exclusion as the simple but very effective mechanism underlying this result. In early rounds, high performers exclude low performers who in consequence ‘learn’ to become high performers.

1 Introduction

Societies continuously face incidents in which efficient coordination is crucial for social welfare (Schelling, 1980; Cooper, 1999). Many of these situations can be described as weakest-link problems, where the agent performing worst determines the outcome of all agents involved. Examples are abundant.¹ For instance, global public goods often have a weakest-link characteristic (Sandler, 1998; Nordhaus, 2006). In the fight against outbreaks or the spread of infectious diseases such as SARS, avian influenza, swine influenza, or AIDS all affected parties have to invest into precautionary measures. Whether it concerns vaccination on the individual level or the provision of medication or health education on the state level, it is the party which exerts the lowest effort that largely determines the chances of outbreak or eradication of such a disease. A similar reasoning holds for the protection of computer or other infrastructure networks and the threat of terrorist attacks on airplanes. Hackers or viruses usually enter weakly protected network nodes and use them as stepping stones to intrude further into the network. Similarly, potential terrorists may enter a plane in countries with weak airport security measures.

An illustrative example from organization economics is provided by Camerer (2003, p.381), who describes the coordination problem of airport ground crews. There different teams are responsible for different tasks and the slowest team determines when the aircraft is ready for take-off. Similarly, in team production along an assembly line the slowest worker determines the speed of production (Brandts and Cooper, 2006). Groups of co-authors with complementary tasks are yet another example. Obviously, the slowest co-author determines how fast the paper is finished and the sloppiest one its overall quality. More examples of weakest-link situations in professional organizations can be found in Camerer (2003, pp.381-382).

The common feature of these examples is that players, on the one hand, have an incentive to coordinate on high efforts, which implies high individual and group welfare, but, on the other hand, also face considerable strategic uncertainty, because one single ‘trembling’ player suffices to cause substantial losses for all. Crucially, however, some of the examples also differ in an important aspect. Members of work teams in firms are usually bound to their team mates and

¹In the economics literature weakest-link problems were introduced by Hirschleifer (1983). He describes Anarchia, a fictitious island with no governing body, on which each citizen owns a wedge-shaped sector. In order to prevent the island from occasional floods, individual citizens build dikes along their land’s coastline. The topography of Anarchia is flat, implying that if the sea overflows just one dike the whole island is flooded. Hence, the lowest and weakest dike determines the level of flood protection which Anarchia’s society may expect.

can—at least in the short term—hardly avoid interaction with other members. This is different for actors in the global public goods and network examples and members of freely associated work teams who often can choose their interaction partners. Governments may restrict free travel from and to countries with weak precautionary and security measures,² network system administrators may restrict access to sufficiently safe network nodes, and co-authors may terminate cooperation with too slow or too sloppy colleagues.

In this paper we experimentally demonstrate that the possibility to choose interaction partners boosts efficiency in weakest-link (aka minimum effort) games. The existing experimental evidence on such games shows that, when played in fixed groups, efficient outcomes are difficult to achieve and infeasible when groups are large enough.³ The seminal papers by Harrison and Hirshleifer (1989) and Van Huyck et al. (1990, VHBB, henceforth) indicated that only in very small groups, consisting of just two members, substantial coordination on the most efficient equilibrium occurs. For larger groups of size 14 to 16 coordination quickly converged towards the least efficient equilibrium. This regularity of efficient coordination in only very small groups and inefficient coordination in larger groups was replicated in many experimental studies building on VHBB (e.g., Knez and Camerer, 1994; Cachon and Camerer, 1996; Weber et al., 2001; Brandts and Cooper, 2006; Weber, 2006; Brandts and Cooper, 2007; Brandts et al., 2007; Hamman et al., 2007; Chaudhuri et al., 2009; Kogan et al., 2011).⁴

Some of these studies have shown that decreasing costs or increasing payoffs when playing an ‘efficient action’ can help to improve coordination on more (but not fully) efficient equilibria in groups of size 4 (Goeree and Holt, 2001; Brandts and Cooper, 2006, 2007; Brandts et al., 2007; Hamman et al., 2007). Introducing the possibility of communication and leadership helps to coordinate on efficient equilibria only if groups are very small and leads to mixed results for somewhat larger groups (Cooper et al., 1992; Charness, 2000; Weber et al., 2001; Blume and Ortmann,

²One might argue that in case of a disease outbreak viruses may enter a country via an indirect route. Note, however, that this is unlikely if contacts are kept only among countries with strong precautionary measures or when containment of the disease is a major part of the precautionary program.

³For an excellent survey of the pre-2007 literature on weakest-link and other coordination experiments, see Devetag and Ortmann (2007).

⁴Goeree and Holt (2001) and Chen and Chen (2011) provide evidence that even when played in pairs subjects may be unable to reach efficient outcomes provided the costs of higher effort are large enough or the game is repeated with different partners.

2007; Brandts and Cooper, 2007; Chaudhuri et al., 2009).⁵ Lastly, using a smart design, Weber (2006) reports that slowly increasing the group size by exogenously adding players can reliably achieve larger than minimally—but rarely fully—efficient outcomes in groups up to size 9. Further, in about one-third of the investigated groups fully efficient equilibria in groups of size 12 are occasionally observed.

Although some of the previously investigated elements can help players to coordinate more efficiently in weakest-link games, the fact remains that first-best efficiency is hardly achieved. Especially for groups with more than 7 members stable fully efficient outcomes are virtually absent. This is puzzling because outside the experimental laboratory we observe much larger groups that seemingly have managed to coordinate efficiently.

In this paper we show that the possibility of freely choosing interaction partners has a dramatic positive impact on achieved efficiency in weakest-link games, even in large groups. More specifically, we experimentally test behavior of subjects in weakest-link games, à la VHBB, without and with neighborhood choice, in groups of size 8 and 24. The latter is—to the best of our knowledge—the largest group size investigated in the laboratory. We implement two classes of treatments. In our *BASELINE TREATMENTS* (BTs) we replicate the VHBB set-up. Each player in a group simultaneously chooses an integer number (‘effort’) between 1 and 7. A player’s own chosen effort determines her individual cost and the lowest effort chosen in the group the benefit each group member receives. The (pure strategy) Nash equilibria are those where all choose the same effort and can be Pareto ranked from all choosing 1 (least efficient equilibrium) to all choosing 7 (most efficient equilibrium). Our *NEIGHBORHOOD CHOICE TREATMENTS* (NTs) are identical to the BTs, except that, (i) interaction between any two players requires mutual consent, and (ii) the minimum effort chosen in one’s interaction neighborhood determines one’s

⁵In a setting different from VHBB, Berninghaus and Ehrhart (1981, 2001) report that more efficient coordination is correlated with the number of repetitions and with more specific information feedback about past play, respectively. The latter, however, seems not to be a robust result (Engelmann and Normann, 2010). These authors also report that Danish participants have a higher likelihood to coordinate on efficient equilibria in groups up to size 6, with mixed results in groups of size 9. Bornstein et al. (2002) find that when groups have to outperform each other they are more likely to coordinate on more efficient equilibria. Feri et al. (2010) report that if players are groups instead of individuals they achieve more efficient outcomes for groups of size 5. Chen and Chen (2011) show theoretically and experimentally that randomly matched pairs of players are able to coordinate on close to efficient effort levels in groups where players share a (induced) social identity.

benefit. Importantly, when—by mutual consent—each player is in the interaction neighborhood of all other players, the game played in the NTs is equivalent to the game played in the BTs.^{6,7}

Our findings in the BTs are in accordance with the results reported in the literature. Efficient coordination is sometimes observed in groups of size 8, but never in groups of size 24, and over time behavior converges to inefficient equilibria, irrespective of group size. In stark contrast, in the NTs subjects quickly coordinate on the fully efficient equilibrium, where all choose the highest effort level and everybody interacts with everybody else. Furthermore, over time there is no tendency toward less efficient equilibria. This holds for medium sized as well as large groups. We identify exclusion of subjects who choose low effort by those who choose higher effort as the driving force behind these results. For subjects who choose high effort the possibility to exclude provides an often costly but effective way of reducing strategic uncertainty, and for those who initially choose low effort (the threat of) being excluded provides sufficient pressure to opt for high effort in subsequent encounters. Importantly, over time, when eventually all subjects are choosing the highest effort, exclusion becomes obsolete, which in turn boosts overall welfare.

In the remainder of the paper, we first formally introduce the weakest-link game and its neighborhood choice extension in Section 2. Then we describe our experimental design and parameters and present hypotheses in Section 3. This is followed by a description of the experimental procedures in Section 4. In Section 5 we report the results of the experiment and Section 6 concludes. The appendix provides formal derivations of the theoretical benchmarks (Appendix A) as well as the experiment instructions (Appendix B).

⁶There are three experimental papers that are related to our study in that they also allow for endogenous interaction structures in coordination games. Corbae and Duffy (2008) investigate the effect of payoff shocks in a two-stage game where four players first choose the interaction network and then play several rounds of a stag-hunt coordination game. Chen (2011) studies the effect of social identity in dictator games and creates group identity by allowing for endogenous group formation via a ranking mechanism in three-person minimum effort games. In the sociological network literature Corten and Buskens (2010) explore groups of size 8 playing pair-wise stag-hunt games in a dynamic setting where players can remove or add at most one interaction link in each round. Their main interest lies in the effect of different exogenously imposed initial networks on behavior later in the game.

⁷Another more remotely related stream of papers looks into the effect of group formation and partner choice on pro-social and cooperative behavior in social dilemma and public good games (Hauk and Nagel, 2001; Riedl and Ule, 2002; Coricelli et al., 2004; Page et al., 2005; Ahn et al., 2008; Charness and Yang, 2008; Ule, 2008; Ahn et al., 2009; Brandts et al., 2009). The overall picture emerging from these studies is, that pro-social behavior seems to be enhanced when groups are not fixed. However, the strength of the effect depends on the precise institutional details (Riedl and Ule, 2002; Ule, 2008) and in some cases partner choice may even have detrimental effects on pro-social behavior (Brandts et al., 2009).

2 The Weakest-Link Coordination Game

The games we investigate are based on the minimum effort game of VHBB. The BASELINE GAME (BG) is the same as in VHBB and players can only choose between different effort levels. In the NEIGHBORHOOD GAME (NG) we allow players, in addition to their effort choice, to choose their interaction neighborhood by mutual consent. This extension requires an adjustment of the payoff function for the cases where not all group members interact with each other. The BG is a special case of the NG, where the neighborhood of each player is fixed to be the entire group.

2.1 The Baseline Game

Let $N = \{1, 2, 3, \dots, n\}$ be a group of players and $E = \{1, 2, \dots, 7\}$ be a set of effort levels. In the BG, each player simultaneously chooses an effort level $e_i \in E$. Let $s = (e_i)_{i \in N}$ be the strategy profile of all players in the group. Further, let b denote the marginal cost of effort, a the marginal return from the lowest effort in the group, and $a > b > 0$. The payoff of player i is given by

$$\pi_i(s) = a \min_{j \in N} \{e_j\} - be_i + c, \quad (1)$$

where $c > 0$ ensures non-negative payoffs for all strategy profiles. $a > b > 0$ implies that every player has a monetary incentive to align his effort level with the minimum level chosen by the other players. Therefore, the strategy profiles $(\tilde{e})_{i \in N}$ where all players choose the same effort level \tilde{e} are the pure strategy Nash equilibria.⁸ Furthermore, these Nash equilibria can be Pareto-ranked from the lowest effort to the highest effort equilibrium, and the strategy profile where every player chooses the lowest effort is pairwise risk-dominating any other equilibrium.⁹

2.2 The Neighborhood Game

As in BG each player i chooses simultaneously an effort level $e_i \in E$. Additionally, each player i simultaneously chooses a set of players $I_i \subseteq N \setminus \{i\}$ with whom she would like to interact. For an interaction to actually take place mutual consent is required. That is, two players i and j interact with each other if and only if $i \in I_j$ and $j \in I_i$. Let $s = (s_1, s_2, \dots, s_n)$ with $s_i = (e_i, I_i)$ be a strategy profile in NG. The interaction neighborhood of player i is given by

⁸In line with the experimental literature, we focus on pure strategy equilibria. Equilibria in mixed strategies do exist, however.

⁹Although the concept of risk dominance is not transitive, in general, it is for this particular game (Harsanyi and Selten, 1988).

$N_i(s) = \{j | j \in I_i \wedge i \in I_j\}$. The size of i 's neighborhood, i.e., the number of players i is interacting with, is denoted by $n_i = |N_i(s)|$.

In contrast to BG, in NG players do not necessarily interact with all other players in the group. This requires a definition of payoffs in such situations. The payoff function in NG should be comparable to the payoff function in BG and also reflect the tradeoff players face when choosing to interact between more or less interaction partners. More interaction partners in a weakest-link game clearly increase strategic uncertainty.¹⁰ Hence, to avoid trivial outcomes, there also has to be a potential benefit accruing from interacting with more people.¹¹ A natural way to conform to these requirements is to let a player's benefit depend on the minimum effort in the player's interaction neighborhood and to make the payoff proportional to the neighborhood size. To achieve this we introduce the relative neighborhood size $\frac{n_i}{n-1}$ into the payoff function of BG, such that a player's payoff in NG is given by

$$\pi_i(s) = \frac{n_i}{n-1} \left[a \left(\min_{j \in N_i(s) \cup \{i\}} \{e_j\} \right) - be_i + c \right]. \quad (2)$$

Importantly, for the case where the neighborhood of each player is exogenously fixed to be all other players (i.e., for all i , $I_i = N \setminus \{i\}$ and $i \in I_j$ for all $j \neq i$) the payoff functions in NG and BG coincide. This guarantees comparability of incentives between the games when all interact with all in NG.¹²

3 Design and Hypotheses

Our experiment comprised two BASELINE TREATMENTS (BTs) where we implemented the BG with groups of size 8 and 24, respectively, and two NEIGHBORHOOD TREATMENTS (NTs) where we implemented the NG with the same two group sizes. In each treatment subjects played the

¹⁰Recall the almost universal breakdown of efficient coordination in weakest-link game experiments with groups of size larger than 8, reported on in the Introduction.

¹¹The examples in the Introduction also point to this feature. For instance, having more complementary trade and travel links likely increases potential benefits, better connected computer networks speed up information flow, and more co-workers with complementary talents likely increase product quality. Surely, there will be some upper bound on the number of beneficial links, an issue we ignore here.

¹²A self-evident alternative payoff function in NG would have the proportionality factor applied only to the benefits and not to the costs. While in applications both scenarios are conceivable, there are good reasons to assume that costs increase with neighborhood size (e.g., due to communication costs with neighbors, maintenance costs of infrastructure, costs of diplomacy with trading partners, etc.).

Table 1: Payoffs of Player i

	$\min_{j \in N_i(s) \cup \{i\}} \{e_j\}$						
	7	6	5	4	3	2	1
7	130	110	90	70	50	30	10
6	-	120	100	80	60	40	20
5	-	-	110	90	70	50	30
e_i 4	-	-	-	100	80	60	40
3	-	-	-	-	90	70	50
2	-	-	-	-	-	80	60
1	-	-	-	-	-	-	70

Note: In the table neighborhood size is ignored. In BT the neighborhood coincided with all other group members and actual payoffs coincided with the table entries. In NT the payoffs in the table were multiplied by the fraction of players i interacted with relative to all other members in the group.

corresponding game repeatedly for 30 rounds in fixed matching groups. To assure anonymity, subjects did not get to know the identity of the other group members. They were referred to themselves as me and to the others in their group with capital letters A , B , C , etc. For each subject these identifiers remained fixed throughout the experiment. In BT, in each round each subject interacted with all other group members and chose, simultaneously and independently, an effort level.

The parameters of the payoff function were the same as in VHBB: $a = 20$, $b = 10$, and $c = 60$. Table 1 shows the corresponding payoff table of a player i . In NT, subjects in each round did not only choose an effort level, but also decided simultaneously, regarding each other group member, whether to propose an interaction or not. For any pair of subjects an interaction took place only if both proposed to interact with each other. Figure 1 shows an example screenshot for NT. (For an example screenshot of BT, see Figure B.1 of the experiment instructions provided in Appendix B.) Note, that two subjects could interact with each other while having been involved in only partially overlapping interaction neighborhoods. For instance, in the situation depicted in the screenshot A and G interact with each other. Yet, A 's interaction neighborhood comprises next to G only subject me , while G interacts also with subjects B and C .

In all treatments, when making their decisions, subjects had access to the complete history of their own and other group members' actions.

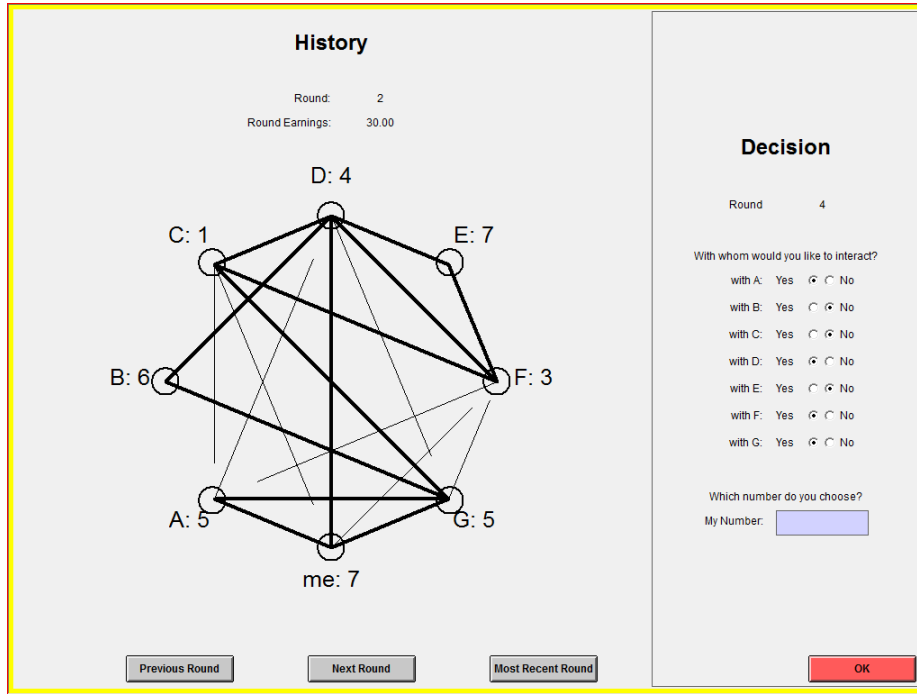

Figure 1: Decision Screen in the Neighborhood Treatment (Group Size 8). Note: On the left side of the screen subjects could browse through the previous outcomes. The thick lines between two letters indicate that the corresponding pair of subjects interacted in that round (i.e., both subjects indicated that they wish to interact with each other). Thin lines between two letters mean that only one subject proposed to interact and interaction did not take place (e.g., subject *C* wanted to interact with subject *A*, but *A* did not wish to interact with *C*). In order to save some time and effort costs, the interaction decisions from the previous round were used as default for the current round. The decision screens in the BT looked similar except that there were interaction lines between all pairs of letters shown on the left side and the decision was only about the effort level.

3.1 Theoretical Benchmark Predictions

Theoretically the introduction of neighborhood choice worsens the coordination problem in the weakest-link game. Indeed, since for an interaction to take place mutual consent is required the number of equilibria is huge and strongly increases with the number of players. For instance, any fragmentation of the set of players into internally fully connected but pair-wise isolated neighborhoods, where within each neighborhood the same effort is chosen, can be supported by a Nash equilibrium. Therefore, to achieve a more refined theoretical benchmark prediction we apply the concept of stochastic stability under a myopic best response dynamic (Young, 1993, 1998). We prefer stochastic stability over other possible equilibrium refinements because (a) its

dynamic structure fits well to our experimental design, (b) it has been shown to be a good predictor in simpler 2×2 stag-hunt coordination games (Young, 1998), and (c) its parsimony.¹³

In the following proposition we formulate the theoretical predictions for BG and NG, which also form our first hypotheses regarding behavior in the BTs and NTs.

Proposition 3.1 THEORETICAL BENCHMARK PREDICTIONS.

For our experimental parameters, both, the baseline game and the neighborhood game, have a unique stochastically stable equilibrium under a myopic best response dynamic. In this equilibrium each player’s interaction neighborhood consists of all other players and every player chooses the lowest effort level.

The proof of the proposition is provided in Appendix A, where it is shown separately for BG (Proposition A.7) and NG (Proposition A.5). Note that, while in BG it is assumed that each player is interacting with each other player, in NG this interaction structure emerges endogenously from the stochastic dynamics.

3.2 Behavioral Hypotheses

Stochastic stability is an intuitive and useful concept to predict outcomes but it neglects psychological motivations, as desire for fairness or efficiency, that have been shown to robustly affect behavior (see, e.g., Fehr and Schmidt, 1999; Bolton and Ockenfels, 2000, on fairness, and Charness and Rabin, 2002; Engelmann and Strobel, 2004, on efficiency). This suggests the application of models of generalized (or social) preferences. Unfortunately, however, these models are notoriously bad in producing tight predictions. In fact, generally the application of such models increases the number of equilibria in one-shot games. Moreover, Oechssler (2011) has shown that even for one-shot games with a unique equilibrium the uniqueness property of the subgame perfect equilibrium is lost in its finite repetition when allowing for social preferences.

¹³Jackson and Watts (2002) theoretically analyze simpler 2×2 coordination games with a similar dynamic structure and find that play converges to the stochastically stable equilibrium where everybody is playing the risk-dominant equilibrium with everybody else. Crawford (1995) provides a discussion on the (in-)appropriateness of other equilibrium refinement concepts. He also suggests and analyzes a general learning model to explain the data of VHBB. This model however requires a one-dimensional strategy space and can, therefore, not be applied to our neighborhood game. Battalio et al. (2001) analyze 2×2 stag-hunt coordination games by applying a logit quantal response equilibrium (McKelvey and Palfrey, 1995). Given the huge strategy space of our NG, application of this concept without imposing strong additional assumptions is infeasible.

Therefore, in the following discussion of the possible effects of preferences for fairness or efficiency we confine ourselves to intuitive and informal arguments.

Fairness considerations are expected to have little bite for equilibrium selection in our weakest-link games. In each BG equilibrium all players earn equal payoffs. In NG there exist equilibria with asymmetric payoffs when isolated neighborhoods have unequal size or when different effort levels are chosen in different isolated neighborhoods. However, there is also a plethora of equilibria where players earn the same.

Efficiency considerations, in the sense of maximizing group earnings, may have an effect, however. In the BTs the total (and individual) earnings in a group increase with coordination on higher effort levels. When subjects are sufficiently efficiency seeking this may provide an incentive to choose high effort even when there is uncertainty about others' effort choices. Yet, the existing experimental evidence indicates that the effect of strategic uncertainty prevails over efficiency seeking in weakest-link games for group sizes investigated in our experiment. Even when full information feedback is given and the game is repeated relatively often the overall picture emerging from the literature is sober: coordination on an effort level different from the lowest effort is difficult to achieve and chosen effort levels deteriorate over time (see Devetag and Ortmann, 2007, and the literature review in the Introduction). We have no *a priori* reason to expect that subjects in our experiment will behave differently.

In contrast to BT, where only effort can be adjusted in response to low effort of other group members, in NT there is also the possibility to stick to a high effort level and to 'exclude' low effort providers from one's interaction neighborhood. Assuming that all other group members do not change their behavior such exclusion can have three short-term effects on earnings. First, if after exclusion one's interaction neighborhood is still sufficiently large individual and group earnings can be higher. Second, individual earnings can be higher but group earnings smaller, because the excluded low effort providers lose earnings. Third, individual and group earnings can be lower because earnings decrease with the size of the interaction neighborhood.

In the first case, myopic earnings maximization and efficiency considerations support the exclusion of low effort providers while keeping own effort high. In the second case only myopic earnings maximization asks for exclusion, while short-term efficiency considerations do not support it. In the third case, neither myopic earnings maximization nor efficiency concerns prescribe the exclusion of low effort providers. However, there can also be long-term effects that may provide an individual and efficiency incentive for exclusion. Exclusion of low effort providers is always costly for the excluded as any interaction leads to positive earnings while no interaction

earns nothing. Hence, a reasonable response to being isolated or having only a small interaction neighborhood is to increase effort, perhaps, to signal to other subjects that one has ‘learned one’s lesson’. For excluding high effort providers this can give an incentive to propose to interact again, because *ceteris paribus* individual and group earnings increase with neighborhood size. In this way, high effort neighborhoods may gradually grow endogenously, while keeping strategic uncertainty low through the threat of individually severing interactions with low effort providers.¹⁴ In summary, we arrive at the following behavioral hypotheses.

Hypothesis 3.2 BEHAVIORAL HYPOTHESES.

- (a) *In the baseline treatment, behavior will converge towards the risk-dominant lowest-effort equilibrium.*
- (b) *In the neighborhood treatment, interaction neighborhoods will increase over time and behavior will converge towards the Pareto-dominant highest-effort equilibrium.*

4 Experimental Procedure

All experimental sessions were conducted at the Behavioral and Experimental Economics Laboratory (BEELab) at Maastricht University. A majority of subjects were students of business (53 percent) and economics (25 percent) while the rest came from other programs (22 percent). All participants were recruited through email announcements and announcements on students’ intranet. Each subject only participated in one experiment session.

The experiment was computerized using z-tree experiment software (Fischbacher, 2007). To ensure anonymity and avoid communication during the experiment subjects were seated in sight-shielded cubicles. Thereafter, subjects received written instructions which they could study at their own pace. For clarifications they could ask questions in private. The experiment did not start before all subjects had correctly answered a series of comprehension questions (see Appendix B for the instructions).

For groups of size 8 we conducted four sessions with BT and five sessions with NT, each with two matching groups of 8 subjects.¹⁵ For the large groups with 24 members we ran three sessions

¹⁴Note, that the potential growth process is similar to the one investigated by Weber (2006), with the important differences that in our case (i) neighborhoods grow *endogenously* (if they grow), (ii) not all players are necessarily in the same neighborhood, and (iii) neighborhoods may also shrink endogenously.

¹⁵We had also planned five sessions for the BT but had to cancel one because of some no-shows.

where we implemented the baseline game (BT-XL) and three sessions with the neighborhood game (NT-XL), each session with one group.

Subjects were paid according to their performance in the experiment. In the experiment all earnings were calculated in points which were converted into cash (20 points = € 0.10) and confidentially paid out immediately after the experiment. In the sessions with the medium sized groups participants earned on average €14.76. A typical session in the BT and the NT lasted around 60 and 80 minutes, respectively. In the sessions with the large groups average earnings were € 12.30. Since the XL treatments sessions took about 30 minutes longer subjects were compensated with an additional € 5.– lump-sum in these sessions.

5 Results

We first report on the results for groups of size 8. We start with the presentation and comparison of effort choices in BT and NT, followed by a discussion of the endogenously formed interaction neighborhoods and the role of exclusion in NT. Thereafter, we present results on the achieved efficiency in both treatments. Finally, we report and discuss the results in our large group treatments BT-XL and NT-XL.

5.1 Effort Levels Without and With Neighborhood Choice

In the experiment we collected data from eight groups in BT and ten groups in NT. Each group forms an independent observation and, if not stated otherwise, our statistical tests are based on aggregated measures of these independent groups. All tests are two-sided.

Figures 2(a) and 2(b) show for both treatments how the cumulative distribution of effort levels develop over time. In the first round, we observe little difference between treatments. The average effort level is 5.66 in BT and 5.99 in NT. A Mann-Whitney (MW) test applied to the individual first round effort choices does not reject the hypotheses of equality ($p = 0.8919, n = 144$).¹⁶ Despite their similarity in the first round, the chosen effort levels show very different dynamics in the two treatments. In BT the frequency of the lowest effort (11 percent in round 1) is strongly increasing over time and becomes the most frequent choice as of round 19. The frequency of the highest effort level deteriorates over time from 64 percent to about 30 percent in the last few rounds. In NT, in contrast, the frequency of the lowest effort never reaches above 4 percent,

¹⁶The distributions of effort levels are not identical though. In BT there is more mass on the extreme effort levels (Fisher exact test, $p = 0.027, n = 144$).

(a) Baseline Treatment

(b) Neighborhood Treatment

Figure 2: Cumulative Distribution of Efforts across Rounds (Group Size 8)

while the frequency of the highest effort level strongly increases over time from about 60 percent in the first round to almost 100 percent in later rounds. In fact, as of round 4, its frequency is mostly above 96 percent and never falls below 88 percent.

This impression of opposite dynamics in effort choices in the two treatments is corroborated by Jonckheere-Terpstra (JT) tests.¹⁷ The tests show that in BT the frequency of effort level 1 is significantly increasing over rounds ($p = 0.0001, n = 8$), while the frequencies of effort levels equal to or larger than 4 are significantly decreasing ($p \leq 0.0009, n = 8$) over time. In NT, in contrast, only the frequency of effort level 7 is significantly increasing ($p < 0.0001, n = 10$), while the frequencies of all other effort levels decrease or do not change significantly.¹⁸

Figure 3 shows that the average and average minimum effort levels exhibit similarly clear treatment effects. Across rounds, both measures are clearly larger in NT than in BT. The average effort and average minimum effort in NT are 6.85 and 6.27, respectively, while they reach only 4.00 and 2.93, respectively, in BT. These differences between treatments are highly significant (average effort: $p = 0.0010$, minimum effort: $p = 0.0033$, MW tests, $n = 18$). The figure also

¹⁷The Jonckheere-Terpstra test is a nonparametric test for ordered differences of a response variable among classes (Pirie, 1983). Here it tests the null hypothesis that the distribution of the frequency of a given effort level does not differ among rounds. The alternative hypothesis is that there is an ordered difference among rounds. That is, if $f(e)_i^t$ denotes the frequency of effort level i in round t then $f(e)_i^1 \leq f(e)_i^2 \leq \dots \leq f(e)_i^{29} \leq f(e)_i^{30}$ (or $f(e)_i^1 \geq f(e)_i^2 \geq \dots \geq f(e)_i^{29} \geq f(e)_i^{30}$) with at least one strict inequality.

¹⁸In all instances similar results are found with Cuzick's (1985) test for trend (using STATA 10.1's nptrend implementation).

Figure 3: Average and Minimum Efforts across Rounds (Group Size 8).

Note: Minimum effort is the average of minimum efforts across groups.

shows that effort levels exhibit very different dynamics and that the treatment differences become more pronounced over rounds. JT tests confirm that average efforts are significantly decreasing in BT ($p = 0.0001, n = 8$) but significantly increasing in NT ($p < 0.0001, n = 10$). Similarly, minimum effort levels stay at low levels in BT ($p = 0.6030, n = 8$) but significantly increase in NT ($p < 0.0001, n = 10$).

At the group level we observe that in BT three of the eight groups manage to coordinate on the highest effort during rounds 13 to 24 and one group manages to secure a minimum effort of 3 towards the end of the experiment. The average effort of the four remaining groups quickly approaches effort level 1. Although, chosen efforts do not fully converge to the lowest possible one in all investigated groups, by and large, the observed levels and downward dynamics are in keeping with previous findings in the literature (cf. Devetag and Ortmann, 2007). Overall, the observed behavior tends to confirm our benchmark and behavioral hypotheses regarding BT.

In NT in nine of the ten investigated groups minimum effort converges to the highest possible level of 7 within the first ten rounds. In the remaining group the average effort level is never below 6 from round 10 onwards. This clearly rejects our benchmark hypothesis and confirms our behavioral hypothesis regarding effort levels in NT.¹⁹

¹⁹In BT as well as NT we observe an endgame effect. In BT, two of the three groups which achieve the highest effort in some rounds show such an effect. In one group it is due to one player deviating to effort level 5 in the last round while in the other group it set in already in round 25 when one subject starts to decrease the effort level and is joined by all other group members save two. In NT, an endgame effect is observed in six groups. In

5.2 Size and Development of Interaction Neighborhoods

In NT, where interaction choices are endogenous, it is important to know whether interactions actually take place, because only then high effort levels also have a high economic return. Recall that, for any pair of subjects an interaction proposal results in actual interaction only if both sides propose an interaction. If a pair of subjects does not interact this can be due to either mutual or unilateral exclusion (i.e., either none or only one of both involved subjects proposes to interact with each other).

Figure 4: Frequency of Interactions and Exclusions across Rounds (Group Size 8).

Figure 4 depicts the frequencies of these three possible situations over time. In the first round, on average, 99 percent of all possible interactions are proposed and 78 percent actually take place. Thereafter, there is a slight decrease in the frequency of actual interactions which reaches its minimum of 74 percent in round 3. From there onwards, this frequency is almost monotonically and significantly increasing over rounds ($p < 0.0001$, JT test, $n = 10$) and as of round 9 it never drops below 94 percent. This increase in actual interactions is accompanied by a simultaneous decrease in the frequency of unilateral exclusions ($p < 0.0001$, JT test, $n = 10$), which decreases to practically zero.²⁰

five of these groups, the effect is caused by only *one* player deviating from the highest effort and in one group it was caused by four players deviating. In four of these six groups, the end game effect occurred in the last round and in two groups it set in in rounds 28 and 29, respectively.

²⁰In fact, as of round 10, in all but one group all possible interactions take place in each round. The one group where sometimes not all members interact with each other is the same group that do not fully settle on everybody always choosing the highest effort of 7. Recall, however, that also in this group averaged effort never falls below 6.

5.3 Exclusion as Efficiency Enforcement

Here we examine if low effort providers are excluded by higher effort providers and, if yes, whether being excluded makes the former to increase subsequently chosen effort levels. If that turns out to be the case it would explain the observed parallel dynamics of effort levels and interaction frequencies.

Specifically, we look at the changes in dyadic relationships for all pairs of group members, i and j , and their effort choices in all three-rounds intervals from $t - 1$ to t and $t + 1$. We do so in three steps. First, we compare the effort levels of i and j in $t - 1$. Second, we analyze whether j excludes i from her interaction neighborhood in t and how this depends on the chosen effort levels in $t - 1$. Third, we check how the chosen effort level of i in $t + 1$ compares with her effort level in $t - 1$, and how a change in effort depends on having been a low effort provider in $t - 1$ and on being excluded in t .

For the first step we categorize all dyadic relations into three distinct classes in dependence of the relative efforts of i and j in $t - 1$. The first class includes all cases where i provided at least as high an effort as j ($e_i \geq e_j$). The second class consists of the cases where i provided a lower effort than j but a higher effort than the lowest effort in j 's neighborhood ($e_i < e_j$ but $e_i > \min_{k \in N_j} \{e_k\}$). The third class includes the cases where i 's effort was lower than j 's and also the lowest effort in j 's neighborhood ($e_i < e_j$ and $e_i = \min_{k \in N_j} \{e_k\}$). In the second step we examine for each of these classes the frequency of exclusion of i by j in round t .

The upper panels, $t - 1$ and t , of Table 2 report the results. Panel $t - 1$ restates the introduced classes of relative efforts between i and j . Panel t reports for each class the frequency (in percent) of severed links, i.e., the exclusion rate, together with the number of cases in parentheses. From the leftmost column it can be seen that, when i chooses an effort level that is not lower than the effort level of j , the exclusion rate is negligible (0.6 percent). In stark contrast, when i chooses a lower effort level than j , but is not the lowest effort provider in j 's interaction neighborhood, the risk of being excluded from j 's neighborhood is quite high (23.6 percent) and further increases to 38.5 percent when i is the lowest effort provider in j 's neighborhood (middle and rightmost columns, respectively). To test whether these differences in exclusion rates across effort classes are statistically significant, we calculate the exclusion rates for each class and each independent matching group separately and apply a Wilcoxon signed-rank test. All three pairwise comparisons are significant ($0.6 < 23.6$, $p = 0.039$, $n = 8$; $23.6 < 38.5$, $p = 0.016$, $n = 8$; $0.6 < 38.8$, $p = 0.002$,

Table 2: Exclusion Rates and Responses to Exclusion.

$t - 1$	Effort of i relative to effort of j and efforts in j 's neighborhood					
	$e_i \geq e_j$		$e_i < e_j$ but $e_i > \min_{k \in N_j} \{e_k\}$		$e_i < e_j$ and $e_i = \min_{k \in N_j} \{e_k\}$	
t	exclusion rates (in percent)					
	0.6 (89/14738)		23.6 (21/89)		38.5 (105/273)	
$t + 1$	i 's response (in percent)					
	$j \in I_i$	$j \notin I_i$	$j \in I_i$	$j \notin I_i$	$j \in I_i$	$j \notin I_i$
$e_i \uparrow$	11.8 (9)	2.6 (2)	71.4 (15)	9.5 (2)	61.6 (61)	10.1 (10)
$e_i =$	68.4 (52)	14.4 (11)	4.8 (1)	4.8 (1)	18.2 (18)	0.0 (0)
$e_i \downarrow$	1.3 (1)	1.3 (1)	9.5 (2)	0.0 (0)	10.1 (10)	0.0 (0)

Note: In panel t , number of cases where exclusion takes places and total number of cases in parentheses. In panel $t + 1$, $j \in I_i$ ($j \notin I_i$) indicates the cases where a subject i excluded in t by j proposes (does not propose) an interaction link to its excluder j in $t + 1$; number of cases in parentheses.

$n = 10$).²¹ Hence, higher effort providers indeed frequently exclude lower effort providers from their interaction neighborhoods.

In the third step, we examine whether the observed exclusion actually affects subsequently chosen effort levels of excluded subjects. To this end, we investigate the change in chosen effort levels from period $t - 1$ to $t + 1$ for those cases where i was excluded in round t . An excluded subject can react in two dimensions. First, it may keep the interaction proposal to j ($j \in I_i$) or avoid interaction with j ($j \notin I_i$) in $t + 1$. Second, it may not change the effort level ($e_i =$), increase it ($e_i \uparrow$) or decrease it ($e_i \downarrow$).

Panel $t + 1$ of Table 2 reports the results.²² Interestingly, excluded subjects overwhelmingly keep their interaction proposal with those who excluded them. In between 81.5 percent (for

²¹The differences remain significant at the 5 percent level also after correcting for multiple comparisons using the false discovery rate procedure (Benjamini and Hochberg, 1995).

²²Note that the sum of cases in round $t + 1$ can be lower than in round t because for $t = 30$ no further round exists.

$e_i \geq e_j$) and 89.9 percent (for $e_i < e_j$ and $e_i = \min_{k \in N_j} \{e_k\}$) of the cases excluded subjects keep their interaction proposal with the excluding subject (see columns $j \in I_i$ in Table 2, panel $t + 1$). Further, low effort providers (i.e., when $e_i < e_j$) strongly respond to exclusion with an increase in effort levels. Specifically, in 80.9 and 71.7 percent of the cases an excluded low effort provider increased her effort in response to being excluded (see, Table 2, row $e_i \uparrow$ for the second and third relative effort category, respectively). If a subject was excluded although it did not provide less effort than the excluder then effort mostly stayed the same (82.8 percent, see row $e_i =$ for the first relative effort category).²³ Thus, exclusion indeed makes low effort providers subsequently increase their effort levels and does not discourage high effort providers.

As discussed in Section 3.2, exclusion of low effort providers, while keeping own effort level high, can have different short-term effects on the excluding subject’s earnings. First, it may increase earnings because exclusion can increase the minimum effort in the remaining neighborhood, which may overcompensate the loss from fewer interactions. Second, due to the negative effect on earnings that comes with a reduction in the set of neighbors, an excluding subject may incur losses in the short-term. In the first case exclusion is consistent with myopic earnings maximization, whereas the second case is reminiscent of costly punishment in public goods games (see, e.g., Fehr and Gächter, 2000). Overall, in a little less than half of all cases (48.2 percent) where a subject drops at least one interaction link to any of her neighbors this leads to an increase in the excluding subject’s short-term earnings. In the remaining 51.8 percent of the cases it actually lowers the short-term earnings of the excluding subjects. Note that, as argued in Section 3.2, in both cases exclusion can be consistent with long-term earnings maximization and efficiency considerations, when excluding subjects assume that those excluded will increase their effort levels in response to exclusion.

In summary, high effort providers often exclude lower effort providers from their interaction neighborhood, even though this sometimes comes at short-term costs. In response, lower effort providers increase their effort levels and are eventually included again. This explains the strong dynamics toward the highest possible effort level of 7 where everybody interacts with everybody else (cf. Sections 5.1 and 5.2).

²³Ideally we could provide a statistical test showing that in comparison to not excluded subjects, those who face exclusion increase effort levels significantly more. However, there are too few cases where low effort providers are not excluded by any neighbor. (Note, that the 23.6 and 38.5 percent refer to the excluding subject j and not to the excluded subject i .)

5.4 Welfare

Failure of (efficient) coordination can be the source of large welfare losses. VHBB distinguish two types of coordination failure. First, players may fail to predict the effort levels of other players and, therefore, fail to coordinate on any equilibrium (individual coordination problem). Second, players may coordinate, but do so on inefficient equilibria (collective coordination problem). In the previous sections we have seen that in both treatments the individual coordination problem is solved over time. However, the collective coordination problem is only solved in NT and, as shown above, the mechanism behind this is exclusion. Yet, whenever a player excludes another player the excluded player loses earnings for sure and the excluding player loses earnings in more than 50 percent of the cases (see above). Therefore, at the outset it is not clear whether the overall earnings in NT are higher than in BT.

In order to examine that, we calculate a group’s welfare as the sum of earnings of all group members. In addition, we calculate the maximally possible welfare where every group member chooses the highest effort level of 7 and interacts with all other group members (‘optimal benchmark’). Figure 5 shows the average welfare levels over time for both treatments as well as the optimal benchmark.

Figure 5: Welfare Levels across Rounds (Group Size 8).

In both treatments average welfare levels are significantly increasing over rounds ($p < 0.0001$, $n = 8$ and $n = 10$, respectively, JT test for trend). In BT this is mainly due to a decrease in the individual coordination problem. That is, subjects learn to coordinate on the same effort level (cf. Section 5.1 and Figure 3). In NT, in contrast, the stark increase in welfare is induced by overcoming both the individual *and* the collective coordination problem. As of round 10 up

to almost the last round welfare is basically identical to optimal welfare. Taken over all rounds, average welfare in NT is economically and statistically significantly larger than in BT (BT: 629.5, NT: 913.1, $p = 0.0129$, $n = 18$, Mann-Whitney test). Hence, endogenous neighborhood choice not only increases effort levels but also welfare.

5.5 Large Groups

The experimental literature discussed in the Introduction unambiguously shows that for groups of size larger than 12, eventual convergence of behavior towards inefficient equilibria is unavoidable. The reason for this sober result is that strategic uncertainty is strongly increasing with group size. Indeed, in fixed groups it usually suffices that one group member deviates to a lower effort to initiate the unravelling of higher effort choices. With our XL treatments—with groups of size 24—we want to test whether neighborhood choice can also successfully ban strategic uncertainty when groups become large.

Figure 6 shows the cumulative distributions of effort levels over rounds for the baseline treatment, BT-XL (panel (a)) and the neighborhood treatment, NT-XL (panel (b)). In the first round, the lowest effort level of 1 is chosen equally infrequent in BT-XL and NT-XL (6.9 percent). The highest effort level of 7 is more often chosen in the NT-XL (65.3 percent) than in the BT-XL (44.4 percent). This translates into a significantly higher average effort in NT-XL than in BT-XL, already in round 1 ($p = 0.0238$, $n = 144$, Mann-Whitney test).

In addition, and even topping the results for groups of size 8, the dynamics of effort choices are dramatically different in the two treatments. In BT-XL the cumulative average frequency of the two lowest effort levels of 1 and 2 quickly increase from 6.9 percent in the first round to at least 90 percent as of round 13, while the average frequency of the highest effort level quickly decreases from 44.4 percent in round 1 to at most 4.2 percent as of round 16. In XL-NT the opposite is observed. The cumulative average frequency of effort levels smaller or equal 6 decreases from 34.7 percent in round 1 to negligible 1.4 percent as of round 9, while the average frequency of the highest effort level 7 increases from 65.3 percent in round 1 to at least 98.6 percent as of round 9.²⁴ JT tests for trend show that in BT-XL the frequency of effort level 1 is significantly increasing over rounds ($p < 0.0001$, $n = 3$), while all frequencies of the higher effort levels are decreasing ($p \leq 0.0010$, $n = 3$, for each level). In NT-XL these tests detect a significant

²⁴The only exception is the very last round where we observe a slight endgame effect. In that round, effort level 7 is chosen with an average frequency of 90.3 percent and effort levels 1 and 2 are chosen with an average frequency of 8.3 and 1.4 percent, respectively.

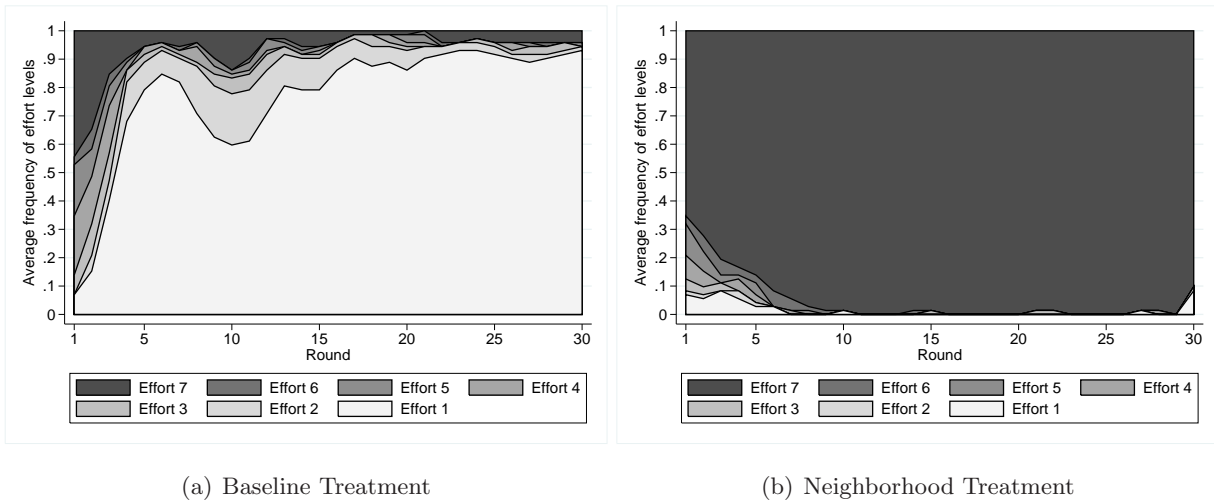

Figure 6: Cumulative Distribution of Efforts across Rounds (Group Size 24).

downward trend for all effort levels strictly smaller than 7 ($p \leq 0.0225$, $n = 3$, for all levels), while the frequency of the highest effort level exhibits a significant trend upwards ($p < 0.0001$, $n = 3$).

Figure 7 shows the average effort levels and the average minimum effort levels for both treatments. Over rounds the average effort is significantly decreasing in BT-XL ($p < 0.0001$, $n = 3$, JT test) but significantly increasing in NT-XL ($p < 0.0001$, $n = 3$, JT test). The average minimum effort in BT-XL does not exhibit any trend because it is at the lowest level of 1 throughout all rounds. In NT-XL this effort statistics shows a significant increase over time ($p < 0.0001$, $n = 3$, JT test). Furthermore, when averaging across rounds, each investigated NT-XL group achieves average and average minimum effort levels that exceed the levels of their counterparts in BT-XL by far (average effort: 1.78 in BT-XL, 6.83 in NT-XL; average minimum effort: 1 in BT-XL, 5.41 in NT-XL). These differences are statistically significant at $p = 0.10$ (MW tests), which is the lowest achievable p -value for the two-sided test, given that the number of our independent matching groups is 2×3 .

Figure 7 indicates an endgame effect which is due to only a few subjects. In the different NT-XL groups 1, 2, and 4, respectively, of the 24 group members deviated from the highest effort level in the last round. The occasional downward movements of the average minimum effort are caused by a single individual in a single group. In the other two groups all members choose the highest effort as of round 10.

The development of actual interactions and unilateral and mutual exclusions is depicted in Figure 8. The picture is qualitatively the same as for groups of size 8 but with a more pronounced

Figure 7: Average and Minimum Efforts across Rounds (Group Size 24).
 Note: Minimum effort is the average of minimum efforts across groups.

dynamics in the first couple of rounds. In the first round, on average 87.8 percent of all possible interactions take place. This frequency sharply decreases to a minimum of 58.7 percent in round 3, after which it monotonically increases. As of round 11 it never falls below 97 percent.²⁵ The overall increasing frequency of interactions and decreasing frequency of unilateral exclusions is corroborated by JT tests ($p < 0.0001$, $n = 3$, for both, interactions and unilateral exclusions).

Figure 8: Frequency of Interactions and Exclusions across Rounds (Group Size 24).

²⁵The deviations from 100 percent are caused by a single subject that repeatedly deviated to lower effort levels and, in consequence, was excluded by some group members.

Exclusion behavior is also very similar to that observed for groups of size 8. Subjects providing a lower effort are excluded by subjects choosing a higher effort. Specifically, in each case where a subject chooses an effort below the highest possible effort level it is excluded by at least one group member. In response to being excluded subjects increase their effort level to the highest level, after which they receive interaction proposals from all group members again.²⁶

In both treatments welfare increases over rounds ($p < 0.0001$, $n = 3$, JT tests). Yet, the opposing dynamics in effort choices between BT-XL and NT-XL together with the convergence toward full interaction in NT-XL implies welfare effects that are strongly in favor of the neighborhood treatment. As of round 6, total welfare achieved in NT-XL is above the one achieved in BT-XL. Furthermore, in BT-XL actual welfare never exceeds 52.5 percent (round 17) of the optimally achievable welfare level, while in NT-XL it almost never falls below 94.7 percent of the optimal level as of round 11. Across all rounds, the achieved average welfare in BT-XL (1492.6) is only 61 percent of the welfare achieved in NT-XL (2443.6). The difference is statistically significant at $p = 0.10$ (MW test). As for effort levels this is the lowest p -value that can be achieved for the two-sided test, given that the number of our independent matching groups is 2×3 .

6 Conclusion

In this paper we study the effect of neighborhood choice on behavior in weakest-link (aka minimum effort) coordination games. Theoretically, the introduction of neighborhood choice, which expands the strategy space, worsens the coordination problem as it hugely increases the number of pure strategy Nash equilibria. Moreover, from an equilibrium selection perspective, neighborhood choice seems irrelevant for the investigated games because the unique stochastically stable equilibrium prescribes that everybody plays the inefficient risk-dominant equilibrium. However, these theoretical considerations neglect that neighborhood choice may provide room for psychological motivations like a desire for efficiency to affect behavior differently than in games played in fixed interaction neighborhoods.

To test the behavioral effect of neighborhood choice we conduct experiments with groups of size 8 and 24. In the baseline treatments with exogenously fixed interaction neighborhoods,

²⁶The only exception is the one subject mentioned in footnote 25. After repeated deviations from the highest effort level some group members became ever more reluctant to interact with this subject and at some point excluded it for good. On average this subject only received 5 (out of 23) interaction proposals per round, whereas the remaining subjects received 21 proposals per round, on average.

we replicate the well known result of a strong tendency toward coordination on inefficient risk-dominant equilibria. The introduction of neighborhood choice completely reverts this trend. We observe a dramatic increase in the ability of players to coordinate efficiently. In fact, for both group sizes, after just a few rounds basically all groups manage to coordinate on the fully efficient equilibrium. This efficient coordination takes place in neighborhoods where all players interact with each other and are, thus, equivalent in size to the failing groups in the baseline treatments. Importantly, efficient coordination is extremely stable and shows no tendency to decay with time. Consequently, in terms of welfare, groups with neighborhood choice achieve about 1.5 times the earnings of groups without neighborhood choice.

We identify exclusion of low effort providers by high effort providers as the simple but effective mechanism that drives the result. When acting in fixed neighborhoods, initially high effort providers usually respond to low effort of their neighbors with a reduction in their own effort. This often initiates a self-confirming process where the outcome gets mired in the inefficient risk-dominant equilibrium. In contrast, neighborhood choice offers the possibility to avoid interaction with low effort providers, retain interaction with high effort neighbors and keep up own high effort. In the experiment we indeed frequently observe such exclusion in early rounds. Importantly, excluded low effort providers learn to choose high effort levels and are eventually included into the interaction neighborhood again. Notably, subjects who exclude often incur short-term costs.

The behavior observed in our experiment indicates a high potential for self-organization on first-best efficient equilibria, provided people are given sufficient freedom in choosing their interaction partners. It suggests that much of the seemingly efficient coordination observed in the field is indeed efficient. Importantly, our experimental results demonstrate that in the behavioral efficient equilibrium actual exclusion will not take place. Hence, in the field, efficiently coordinated groups where no exclusion is observed may still rest on the threat of exclusion. This behavioral equilibrium property also makes it difficult to directly observe the effect of exclusion on coordination in the field. Yet, indirectly coordination failure or inefficient coordination may be traced back to the lack of interaction neighborhood choice.

We view our experiment as a first stepping stone toward a promising research agenda investigating the potential and limits of neighborhood choice in coordination problems. There are many possible directions for future research. First, in some circumstances neighborhood choice can not be individualized. For example, if there is a misbehaving neighbor in the street, one can respond to it by moving to another neighborhood. This, however, implies that one is abandoning also the

nice neighbors who do behave. Another example are work teams where one can choose the team one would like to be a member of but not the team composition itself. Second, physically moving often comes with transactions costs. In our experiment this is reflected by the opportunity costs of not interacting. Yet, the introduction of nominal costs when abandoning an interaction may have other behavioral effects than mere opportunity costs. Third, an obvious candidate for future research is the exploration of information effects. In our experiment subjects possess global information and have perfect recall in the sense that they can access all decisions in all past periods for all members in their group, even if they did not interact with them. An interesting variation would be to give only local information where only effort choices of interaction partners can be observed. Further, there are many more possible directions of research like the evaluation of the effect of other than a proportional increase of the payoff with the neighborhood size or the effect of limits on the number of neighbors one can interact with, to mention just a few.

Last but not least, our results suggest an important implication for the design of organizations and institutions. In particular, it provides a policy dimension that is probably cheaper than increasing the payoff for coordination on the efficient equilibrium (Brandts and Cooper, 2006) and more effective than exogenously growing groups (Weber, 2006).

Appendix

A Theoretical Benchmarks

We show that for our parameter setting the fully interlinked network with every player playing the lowest effort is the unique stochastically stable equilibrium for the minimum effort game with neighborhood choice (NG). Thereafter we show that this also holds for the restricted case of the minimum effort game without neighborhood choice.

A.1 The Game

The analysis rests on a one-shot game where each player simultaneously chooses an effort level and the set of other players whom he or she wants to interact with. The basic elements of the game are:

- $N = \{1, 2, 3, \dots, n\}$ is a finite set of players.
- $E = \{1, 2, \dots, m\}$ is a finite set of effort levels.
- $s_i = (e_i, I_i)$ is the strategy of player i with $e_i \in E$ is the player's chosen effort level and $I_i \subseteq N \setminus \{i\}$ is the set of players with whom i wants to interact with.
- $s = (s_1, \dots, s_n) = ((e_j, I_j))_{j \in N}$ is a strategy profile. Later we will interpret it as a state in a Markovian chain. With $s^{\tilde{e}}$ we denote the strategy profile where every player wants to interact with every other player and all play the same effort \tilde{e} , i.e. $s^{\tilde{e}} = ((\tilde{e}, N \setminus \{j\}))_{j \in N}$.
- $s_{-i} = (s_1, \dots, s_{i-1}, s_{i+1}, \dots, s_n) = ((e_j, I_j))_{j \in N \setminus \{i\}}$ is the vector of strategies of all players except i .
- Given a strategy profile s , players i and j are linked if both want to interact with each other, i.e. $j \in I_i$ and $i \in I_j$. If an interaction proposal of i with j is not reciprocated, i.e. $j \in I_i$ but $i \notin I_j$ then j is called a dangling link of i .
- Given a strategy profile s , the neighborhood of a player i is the set of all players to whom i is linked to, i.e. $N_i(s) = \{j | j \in I_i \wedge i \in I_j\}$. With $|N_i(s)|$ we denote the cardinality of $N_i(s)$, in other words the size of the neighborhood.
- For a given s player i 's payoff is

$$\pi_i(s) = \frac{|N_i(s)|}{n-1} \left[a \left(\min_{j \in N_i(s) \cup \{i\}} \{e_j\} \right) - be_i + c \right]$$

with $a > b > 0$ and $c > 0$.

- Our specific experimental settings are $m = 7$, $a = 20$, $b = 10$ and $c = 60$ for $n = 8$ and $n = 24$, respectively.

A.2 The Process

We follow a variant of the approach of Young (1993,1998). Assume discrete and successive time rounds ($t = 1, 2, \dots$). In each round t every player may play a myopic best response to the other players' strategies of round $t - 1$ with some positive probability σ . This construction constitutes a Markov chain with the state space being the set of all strategy profiles and the transition probabilities depending on σ and the payoffs π . We will show that only states with the complete network and everybody playing the same effort are absorbing states and that no other recurrent class of states exist. Thereafter we take the parametrization of our experimental design and calculate the number of errors which are necessary to get from one absorbing state to the other. We use the method introduced by Young (1993,1998) to show that the state with the complete network and the minimum effort played by all players is the only stochastically stable one.

A.3 Some Useful Observations

To start, we state some almost trivial propositions. We will use them later. The corresponding proofs are straightforward.

Proposition A.1 *Given an outcome $s = ((e_i, I_i), s_{-i})$. Then player i 's payoff is independent of dangling links, i.e. $\pi_i((e_i, I_i), s_{-i}) = \pi_i((e_i, I'_i), s_{-i})$ with $I'_i = \{j | j \in I_i \wedge i \in I_j\}$.*

Proof: Dangling links are not decisive for the neighborhood of a player, i.e. $N_i((e_i, I_i), s_{-i}) = N_i((e_i, I'_i), s_{-i})$. Hence neither the removal nor the addition of dangling links change payoffs. As a corollary we get that any best response remains a best response if dangling links are removed or added. ■

Proposition A.2 *For $N_i(s) \neq \emptyset$ the condition $e_i = \min_{j \in N_i(s)} \{e_j\}$ is necessary for $s_i = (e_i, I_i)$ being a best response to $s_{-i} = ((e_j, I_j))_{j \in N \setminus \{i\}}$.*

Proof: Assume $N_i(s) \neq \emptyset$ and that the condition does not hold, then i can improve his payoff by adjusting e_i to $\min_{j \in N_i(s)} \{e_j\}$ while holding I_i constant. ■

A.4 Absorbing States and Recurrent Classes

Proposition A.3 *A state $s^{\tilde{e}}$ with $s^{\tilde{e}}_i = (\tilde{e}, N \setminus \{i\})$ for each player $i \in N$ and some $\tilde{e} \in E$ is an absorbing state.*

Proof: We have to show that $s_i = (\tilde{e}, N \setminus \{i\})$ is the only best response to $s_{-i} = (s_j)_{j \in N \setminus \{i\}}$ with $s_j = (\tilde{e}, N \setminus \{j\})$.

Removing players from I_i strictly decreases $|N_i(s)|$ and therefore strictly decreases π_i . The marginal payoff change with respect to e_i is $-a + b (< 0)$ if i decreases e_i and $-b (< 0)$ if i increases e_i . Any

combination of changes in effort and interaction also leads to negative payoff consequences. It follows that s_i is the only best response to s_{-i} . This holds for each player. ■

Each of the absorbing states forms a recurrent class. In the following we will show that no other recurrent class exists.

Proposition A.4 *No other recurrent class than those defined by the absorbing states in Proposition A.3 exists.*

Proof: We introduce a hierarchy of sets of states into the state space. Let

S be the set of all possible states.

S' be the subset of S for which in any state s' players who are linked play the same effort level and no dangling link exists. This means that the network induced by s' consists of one or more components with all players within a component are playing the same effort level.

S'' be the subset of S' where in any state s'' the link relation is transitive, i.e. if i is linked to j and j to k then also i is linked to k . This means that the network induced by s'' consists of one or more fully interlinked components without dangling links and with all players within a component are playing the same effort level.

S^a be the set of absorbing states as defined in Proposition A.3.

It is obvious that $S \supset S' \supset S'' \supset S^a$. The last inclusion follows from Proposition A.3, an absorbing state is characterized by the complete network with every player playing the same effort.

The proof comprises three steps. We will show that for each state in the supersets S , S' , and S'' a finite path of best responses into the subsets S' , S'' , and S^a exists which the players follow with positive probability.

Step $s \in S \rightarrow s' \in S'$

Assume state $s \in S$. The following algorithm generates a finite sequence of best responses that occurs with positive probability and leads to a state $s' \in S'$. Assume that players update their strategies one by one.

1. Sort the players into a two lists A and B .²⁷

List A contains players that do not have any dangling link in their strategy and whose effort level is at most the minimum effort level of their neighborhood.

²⁷We chose to have lists rather than sets because list B must enable an order for processing the elements (first in first out principle).

List B contains the other players.

2. Take the first player i from list B and calculate all best responses to s_{-i} . There exists a best response s_i without dangling links and $e_i = \min_{j \in N_i(s)} \{e_j\}$ (see propositions A.1 and A.2). Update player i 's strategy to such a best response and put him at the end of list A . The update of s_i may cause some players in A to violate the A -conditions. Put them at the end of list B .
3. If there are players left in B then continue with step 2.

The generated sequence is finite because for each application of step 2 there is exactly one player moving from B to A . A move of a player i from A to B can only happen if a neighbor j moves from B to A and breaks up a link or decreases his effort level such that $e_j < e_i$. In the first case the link between i and j will be irreversibly deleted.²⁸ In the second case i updates by keeping the link and lowering e_i or by breaking the link. Since E is finite, lowering e_i can only happen a finite number of times before the link has to be broken. Because the breaking of a link is irreversible and there is only a finite number of links to be broken, there can only be a finite number of moves from A to B .

Step $s' \in S' \rightarrow s'' \in S''$

Assume state $s' \in S'$, i.e. N is subdivided into several disjoint components C_1, C_2, \dots, C_k . Each component is (not necessarily fully) linked and is free of dangling links. Each player within a component is playing the same effort level. Consider a component C_l in which effort level \tilde{e} is played. Consider further a player $i \in C_l$ who plays strategy $s_i = (\tilde{e}, I_i)$ with $I_i \subseteq C_l$. Then strategy $s_i = (\tilde{e}, C_l \setminus \{i\})$ is a best response to s_{-i} because adding dangling links do not change payoffs (see Proposition A.1). There is a positive probability that each player is playing this best response and that this happens in each component. This means that we reach a state $s'' \in S''$ where components are fully connected.

Step $s'' \in S'' \rightarrow s^a \in S^a$

Assume state $s'' \in S''$. Assume two disjoint components $\underline{C}, \overline{C} \subset N$ and that each component is fully connected. Each player in \underline{C} and \overline{C} plays effort \underline{e} and \overline{e} , respectively. Without loss of generality assume that $\overline{e} \geq \underline{e}$.

By the condition

$$\frac{|\underline{C}| + |\overline{C}| - 1}{n - 1} (a\underline{e} - b\underline{e} + c) > \frac{|\overline{C}| - 1}{n - 1} (a\overline{e} - b\overline{e} + c) \quad (3)$$

we distinguish two cases:

²⁸Note that only players moving from B to A may change their strategy. Player j who is now in A can only reestablish the link to i , after he has been moved back to B . Since he will be put at the end of the list, i will have deleted the dangling link before j 's next turn.

If condition (3) holds, then a player $i \in \overline{\mathcal{C}}$ prefers to play \underline{e} and to link up to all players in both components rather than to stay with component $\overline{\mathcal{C}}$. Because of Proposition A.1 it happens with positive probability that all players in $\underline{\mathcal{C}}$ will create a dangling link to all players in $\overline{\mathcal{C}}$. Once this happens it becomes a best response for each player from $\overline{\mathcal{C}}$ to connect to all players from $\underline{\mathcal{C}}$ and switch to effort level \underline{e} .

If the converse of condition (3) holds, then

$$\frac{|\underline{\mathcal{C}}| + |\overline{\mathcal{C}}| - 1}{n - 1} (a\underline{e} - b\underline{e} + c) < \frac{|\overline{\mathcal{C}}|}{n - 1} (a\bar{e} - b\bar{e} + c) \quad (4)$$

follows. This means that player $i \in \underline{\mathcal{C}}$ prefers to join $\overline{\mathcal{C}}$, to switch the effort level to \bar{e} and to break up all links to his neighbors from $\underline{\mathcal{C}}$, rather than being connected to both components and to play an effort level of \underline{e} . Because of Proposition A.1 it will happen with positive probability that all players in $\overline{\mathcal{C}}$ will offer to establish a link with all players in $\underline{\mathcal{C}}$. Once this happens it becomes a best response for all players from $\underline{\mathcal{C}}$ to connect to all players from $\overline{\mathcal{C}}$, switch the effort level to \bar{e} and break the links with their old neighborhood. The resulting component is not completely connected but connects completely with positive probability and within finitely many steps (for the proof see step $s' \in S' \rightarrow s'' \in S''$).

The previous paragraphs show that regardless of the result of condition 3 there is a positive probability that two components merge to one fully interlinked component $\underline{\mathcal{C}} \cup \overline{\mathcal{C}}$ where each player plays the same effort level (either \underline{e} or \bar{e}). A repeated application of this part of the proof shows that with finitely many steps and positive probability we reach a single fully interlinked component with all players playing the same effort level; i.e. we reach a state $s^a \in S^a$. ■

A.5 Stochastically Stable Equilibria

So far we have shown that the best reply dynamic almost surely converges to one of the absorbing states, making them the only candidates for stochastically stable equilibria. We continue by determining the number of mistakes that are necessary to move from one absorbing state to a basin of attraction of another absorbing state. First, note that mistakes in the form of breaking links only, cannot lead to a different absorbing state unless players are excluded completely. This requires at least $n - 1$ mistakes. Fewer mistakes are necessary if players change their effort level as well. Note further that if a basin of attraction can be reached with a number of uncoordinated mistakes, it can always be reached with the same number of coordinated mistakes. Therefore, it is sufficient to look at cases where subgroups jointly deviate to another effort level.

Consider the system to be in an absorbing state s^a with N fully interconnected and $e_i = \bar{e}$ for all players i . Assume that d_{\downarrow} players deviate to $\underline{e} < \bar{e}$. The following condition must hold to make other players switching to \underline{e} instead of breaking the links to the deviators:

$$a\underline{e} - b\underline{e} + c \geq \frac{n - 1 - d_{\downarrow}}{n - 1} (a\bar{e} - b\bar{e} + c).$$

This resolves to

$$d_{\downarrow} \geq \frac{(n-1)(\tilde{e} - e)}{\tilde{e} + \frac{c}{a-b}}.$$

Consider d_{\uparrow} players who deviate to $\bar{e} > \tilde{e}$. The following condition must hold to make players switching to \bar{e} and cutting all the links to the players of the lower effort level, instead of not changing the strategy:

$$\frac{d_{\uparrow}}{n-1} (a\bar{e} - b\bar{e} + c) \geq a\tilde{e} - b\tilde{e} + c.$$

This resolves to

$$d_{\uparrow} \geq \frac{(n-1) \left(\tilde{e} + \frac{c}{a-b} \right)}{\bar{e} + \frac{c}{a-b}}.$$

In the remainder we focus on our parameter settings of the experiment. In short this means: $a = 20, b = 10, c = 60, E = \{1, 2, \dots, 7\}$, and $N = \{1, 2, \dots, 8\}$ or $N = \{1, 2, \dots, 24\}$, respectively.²⁹ The following tables show the resistances between the absorbing states, i.e. the number of deviations needed to move from an absorbing state (row entry) to a basin of attraction of another absorbing state (column entry).

For the case of 8 and 24 players, respectively, we get:

group size 8								group size 24							
$r(s^i, s^j)$	s^1	s^2	s^3	s^4	s^5	s^6	s^7	$r(s^i, s^j)$	s^1	s^2	s^3	s^4	s^5	s^6	s^7
s^1	0	7	6	5	5	5	4	s^1	0	21	18	17	15	14	13
s^2	1	0	7	6	6	5	5	s^2	3	0	21	19	17	16	15
s^3	2	1	0	7	6	6	5	s^3	6	3	0	21	19	18	16
s^4	3	2	1	0	7	6	6	s^4	7	5	3	0	21	20	18
s^5	3	2	2	1	0	7	6	s^5	9	7	5	3	0	22	20
s^6	3	3	2	2	1	0	7	s^6	10	8	6	4	2	0	22
s^7	4	3	3	2	2	1	0	s^7	11	9	8	6	4	2	0

Proposition A.5 *For both, the 8-player case and the 24-player case s^1 is the only stochastically stable equilibrium of the minimum effort game with endogenous neighborhood choice.*

Proof: We have to show that s^1 is the state with the minimum stochastic potential. This means that among all rooted trees, those with the minimum total resistance (sum of all resistances among the edges) have the root s^1 .

²⁹There are more general results achievable. For the sake of brevity we focus on our central goal, the calculation of the theoretical benchmark for our experimental settings.

Consider a rooted tree T^m with root $s^m \neq s^1$ and total resistance $r(T^m)$. Then we can construct a new rooted tree T^{m-1} with root s^{m-1} by connecting s^m to s^{m-1} and removing the edge from s^{m-1} to state s^k on the path to s^m . The new tree has total resistance

$$r(T^{m-1}) = r(T^m) + r(s^m, s^{m-1}) - r(s^{m-1}, s^k) \leq r(T^m).$$

The last inequality holds because $r(s^m, s^{m-1}) \leq r(s^{m-1}, s^k)$ as can be verified from the tables.

We can iterate this process till we construct T^1 with root s^1 and total resistance

$$r(T^1) = r(T^2) + r(s^2, s^1) - r(s^1, s^k) < r(T^2).$$

The last inequality holds because $r(s^2, s^1) < r(s^1, s^k)$ as can be verified from the tables.

Hence, for any rooted tree T^m we find a chain of rooted trees such that $r(T^1) < r(T^2) \leq \dots \leq r(T^m)$. Therefore the root of the tree with the minimum total resistance must be s^1 . \blacksquare

A.6 The Case without Neighborhood Choice

For the case without neighborhood choice I_i is restricted to $I_i = N \setminus \{i\}$. A strategy is therefore $s_i = e_i$. Furthermore $N_i(s) = N \setminus \{i\}$ and hence $|N_i(s)| = n - 1$. This reduces the payoff function to

$$\pi_i(s) = a \min_{j \in N} \{e_j\} - be_i + c$$

Proposition A.6 *A state s with $s_i = \tilde{e}$ for each player $i \in N$ and some $\tilde{e} \in E$ is an absorbing state in the minimum effort game without neighborhood choice and no other recurrent class exists.*

Proof: This follows immediately from the restriction $I_i = N \setminus \{i\}$ and Proposition A.2. \blacksquare

The resistance tables for the case of 8 and 24 players, respectively, are:

group size 8								group size 24							
$r(s^i, s^j)$	s^1	s^2	s^3	s^4	s^5	s^6	s^7	$r(s^i, s^j)$	s^1	s^2	s^3	s^4	s^5	s^6	s^7
s^1	0	7	7	7	7	7	7	s^1	0	23	23	23	23	23	23
s^2	1	0	7	7	7	7	7	s^2	1	0	23	23	23	23	23
s^3	1	1	0	7	7	7	7	s^3	1	1	0	23	23	23	23
s^4	1	1	1	0	7	7	7	s^4	1	1	1	0	23	23	23
s^5	1	1	1	1	0	7	7	s^5	1	1	1	1	0	23	23
s^6	1	1	1	1	1	0	7	s^6	1	1	1	1	1	0	23
s^7	1	1	1	1	1	1	0	s^7	1	1	1	1	1	1	0

Proposition A.7 *For both, the 8-player case and the 24-player case s^1 is the only stochastically stable equilibrium of the minimum effort game without endogenous neighborhood choice.*

The proof is identical to the proof of Proposition A.5.

B Instructions and Control Questions

[**Remark:** In the following we present the instructions and control questions for the neighborhood treatment. The instructions for the baseline treatment were identical except the paragraphs marked with [NT] and [*]. Paragraphs with [NT] were only given in the neighborhood treatment. Paragraphs with [*] were given in both treatments but appropriately reformulated for the baseline treatment. A complete set of instructions is available from the authors.]

B.1 Instructions for Groups of Size 8

Introduction

Welcome to this decision-making experiment. In this experiment you can earn money. How much you earn depends on your decisions and the decisions of other participants. During the experiment your earnings will be counted in points. At the end of the experiment you get your earned points paid out privately and confidentially in cash, according to the exchange rate:

$$2 \text{ points} = 1 \text{ eurocent.}$$

It is important that you have a good understanding of the rules in the experiment. Therefore, please read these instructions carefully. In order to check that the instructions are clear to you, you will be asked a few questions at the end of the instructions. The experiment will start only after everybody has correctly answered the questions. At the end of the experiment you will be asked to fill in a short questionnaire. Thereafter you will receive your earnings.

During the whole experiment, you are not allowed to communicate with other participants in any other way than specified in the instructions.

If you have a question, please raise your hand. We will then come to you and answer your question in private.

Explanation Experiment

During the experiment every participant is in a **group of eight**, that is in a group with seven other participants. The group you are in will not change during the experiment. You will not receive any information about the identity of the persons in your group, neither during the experiment, nor after the experiment. Other participants will also not receive any information about your identity.

Each person in your group is indicated by a letter. You will receive the name “**me**”. The other seven persons in your group will be indicated by the letters **A, B, C, D, E, F** and **G**. The same letter always refers to the same person.

The experiment consists of 30 rounds. In each round you can earn points. Your total earnings in this experiment is the sum of your earnings in each of the 30 rounds.

[*] In each round, you - and each other person in your group - will have to make two decisions which will influence your earnings. You have to make a **decision** called “**With whom would you like to interact?**” and a **decision** called “**Which number do you choose?**” Your decisions and the decisions of the other participants in your group will influence your earnings (as well as the earnings of the other group members). These decisions are explained in detail below.

Note: During the whole experiment, during all 30 rounds the other participants in your group will stay the same persons

Decisions (in one single round)

[NT] **Decision: “With whom would you like to interact?”**

[NT] You have to decide with whom you would like to interact. You can **propose** an interaction to any other person in your group and you can make as many proposals as you want. (You can also decide not to make any proposal.) Your interaction proposals - together with the proposals of the other persons in your group - determine with whom you actually interact (in the respective round) as explained below:

- [NT] You will interact with a person to whom you proposed to interact only if the other person also proposed to interact with you. That is, **mutual consent** is needed for an interaction to actually take place.
- [NT] You will not interact with another person if either only you or only the other person proposed to interact.
- [NT] You will not interact with another person if neither of you proposed to interact with each other.

[NT] For convenience we will call those persons in your group with whom you **interact: your neighbors**. Your neighbors are therefore those persons to whom you proposed to interact and who at the same time also proposed to interact with you.

Decision: “Which number do you choose?”

In each round, each person in your group has to choose one number from 1 to 7; i.e. either 1, 2, 3, 4, 5, 6, or 7. Your earned points in each round depend on

1. your **own choice of number**
2. [*] the **smallest number** chosen by your neighbors *and* yourself
3. [NT] the number of neighbors you have

[NT] **Note:** You can not choose different numbers for different neighbors. You can, however, choose different numbers as well as different persons to interact with in the different rounds.

Here is the payoff table:

		Smallest number chosen by your group including yourself						
		7	6	5	4	3	2	1
Your chosen number	7	130	110	90	70	50	30	10
	6	-	120	100	80	60	40	20
	5	-	-	110	90	70	50	30
	4	-	-	-	100	80	60	40
	3	-	-	-	-	90	70	50
	2	-	-	-	-	-	80	60
	1	-	-	-	-	-	-	70

[*] Since one’s choice can be a number from 1 to 7, the smallest number can range from 1 to 7. Your payoff is determined by the cell in the row of “your chosen number” and the column of the “smallest number chosen by your neighbors and yourself”. An example is given below.

[*] In the table there are cells with “-”. This indicates that such a combination of “your chosen number” and the “smallest number chosen by your neighbors and yourself” is not possible. For example, if “your chosen number” is 4, the smallest number chosen by your neighbors and yourself cannot be 7, 6, or 5.

[NT] Your earned points in a round will be the payoff as given in the table multiplied by

$$\frac{\text{number of neighbors}}{7}.$$

[NT] For each person in your group with whom you do not interact (i.e. all persons who are not your neighbors) you earn 0 points. For example, if you have no neighbors in a round, then you earn 0 points in that round.

Examples:

[*] Suppose you have four neighbors. You chose 3 and the smallest number chosen by your neighbors and yourself was 3, you earn $4/7 * 90 = 51 \frac{3}{7}$ points.

[*] Suppose you have three neighbors. You chose 5 and the smallest number chosen by your neighbors and yourself was 3, you earn $3/7 * 70 = 30$ points.

[*] Suppose you have four neighbors. You chose 5 and the smallest number chosen by your neighbors and yourself was 4, you earn $4/7 * 90 = 51 \frac{3}{7}$ points.

[*] Suppose you have three neighbors. You chose 7 and the smallest number chosen by your neighbors and yourself was 4, you earn $3/7 * 70 = 30$ points.

Information about Computer Screen (in one single round)

You now get information about the computer screen that you will see during the experiment. You received a print-out of the computer screen (**Example screen 1**) from us. Take this print-out in front of you. The screen consists of two windows: **History** and **Decision**.

- **History:** This window holds information about past round(s). At the beginning of a new round you will automatically receive information in this window about decisions made in the previous round, (In the example, this is round 2; see upper part of the screen). In the window there are 8 circles, named **me**, **A**, **B**, **C**, **D**, **E**, **F** and **G**. **Me** always refers to you. The letters refer to the other seven persons in your group.
 - [NT] A **thick complete** line between two persons (letters or 'me') indicates that they both proposed to interact with each other, that is they were neighbors and, hence, did actually interact with each other. (See, e.g., the line between **me** and **D** on the example screen).
 - [NT] A **thin incomplete** line between two persons indicates that only one of them proposed to interact. That is, they were not neighbors and, hence, did not interact with each other. Such a line starts on the side of the person that proposed to interact, and stops just before the circle of the person that did not want to interact. (See, e.g., the line between **me** and **F** on the example screen: **me** proposed to interact with **F**, but **F** did not propose to interact with **me**.)
 - [NT] No line between two persons indicates that neither of them proposed to interact. That is, they were not neighbors and hence, did not interact with each other.

- Next to the letters you see numbers between 1 and 7. These numbers indicate the chosen numbers of the persons in your group. The number next to letter A shows the chosen number of A. The number next to letter B shows the chosen number of B and so forth. (For example in screen 1, persons **A** and **G** have chosen number 5, while the persons **me** and **E** have chosen number 7.)
 - At the bottom of this window you find two buttons called **Previous Round** and **Next Round**. You can use these buttons to look at the decisions in all previous rounds. The button **Most Recent Round** brings you back to the last round played.
 - Your **earnings** (in points) in the corresponding round can be found just above the graph next to **Round Earnings**.
- **Decision:** In this window you see which round you are in and here you have to make your decisions.
 1. **[NT] With whom would you like to interact?** Below this question you see the seven letters which refer to the seven other participants in your group. You can propose to interact with another person in your group by clicking the button “yes” (the first button), that is the first button to the right of that person’s letter. If you do not want to interact with a person or if you want to remove a proposal to interact, you activate the button “no”, that is the second button to the right of that person’s letter. **Note:** At the beginning of each new round the buttons (i.e. proposals) you have chosen in the previous round will be activated. In each new round you can change your choices, i.e., proposals (not) to interact in the way described above.
 2. **Which number do you choose?** In the small window next to **My Number** you type in the number you want to choose.

[*] When you are satisfied with all your decisions (that is, with **both** the proposals (not) to interact and your chosen number), you have to confirm these decisions by clicking on the button **“Ok”**.

[*] **Note:** After each round you will receive information about all the decisions made (that is, all interaction proposals made and the number choices) by all persons in your group. All other persons in your group will also receive information about all your decisions. This is the end of the instructions. You will now have to answer a few questions to make sure that you understood the instructions properly. If you have any questions please raise your hand. After you have answered all questions please raise your hand. We will then come to you to check your answers. The experiment will begin only after everybody has correctly answered all questions.

If you are ready please remain seated quietly.

Figure B.1: [BT] Example screen 1

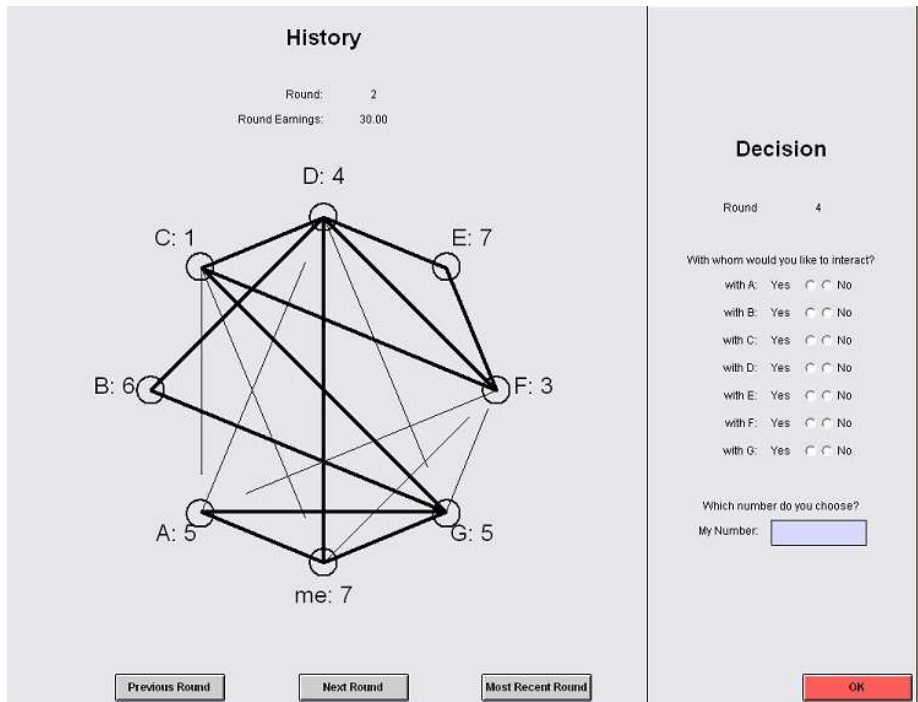

Figure B.2: [NT] Example screen 1

[NT] With whom did person E interact in the previous round? In other words, who were the neighbours of person E?

○ ○ ○ ○ ○ ○ ○

Me A B C D F G

B.2 Instructions for Groups of Size 24

[**Remark:** The instructions for large groups were equivalent to the smaller group instructions, except that subjects were called “**me, N1, N2, ..., N23**” rather than “**me, A, B, ..., G**”, the calculation examples have been modified, and the layout of the history window has been slightly modified.]
